Chapter 1

Introduction

"Predicting the future isn't magic, it's Artificial Intelligence"
— Dave Waters

1.1. Motivation and Objectives

In recent years, deep learning has revolutionized generative tasks in fields like image synthesis, natural language processing, and audio production. Within music, research has generally split into *symbolic* approaches (focusing on note events, pitches, and durations in formats like MIDI) and *non-symbolic* approaches (focusing on raw audio waveforms or spectrograms).

Commercial digital audio workstations (DAWs) and synthesizers already allow users to generate audio with great precision. However, these are often not driven by *deep-learning*–based methods. Moreover, there is a compelling interest in exploring new audio possibilities achieved by *learned* latent representations, e.g., timbres or articulations that might not exist in standard synthesizer libraries.

This Bachelor's Thesis therefore focuses on the implementation of a **Conditional Variational Autoencoder (CVAE)** for directly generating non-symbolic musical notes. Through conditioning, guiding the network with desired musical parameters—such as approximate pitch, instrument type, or intensity—should be feasible. The aim is to combine the *flexibility* and *freshness* of learned audio representations with the *usability* of a straightforward interface that lets users "play" with different configurations to generate sounds. While the results may not surpass the polish or versatility of commercial synthesizers, such a model can reveal new pathways for interactive sound design and serve as a research-driven educational tool.

In any way, we would like this project to serve as an introduction and guide for students or anyone interested in the use of deep learning in music. While we do not assume extensive knowledge from the reader, we also will not go into excessively detailed explanations in order to keep the text accessible.

1.2. Work Plan

This section describes the work plan to follow in order to achieve the objectives outlined in the previous section.

(Pongo aquí esto mejor yo creo) We will need to define a metric for the loss function, in order to quantify how good the sample generation provided by the CVAE is.

Chapter 2

State of the Art

In this chapter, we aim to first provide a brief overview of the evolution of algorithmic composition and, secondly, explore non-symbolic (i.e., low-level) music generation more in depth.

2.1. Brief history of algorithmic composition

Algorithmic composition is the process of using some formal process to make music with minimal human intervention (Alpern, 1995) and can be divided into two main categories: *non-computer-aided* and *computer-aided* methods. The reader should note the following sections are nothing but a succint run-through of algorithmic composition and will necessarily be uncomplete in terms of its content.

2.1.1. Non-computer-aided methods

Algorithmic composition dates back thousands of years. In Ancient Greece, philosophers such as Pythagoras (500 B.C.) viewed music as fundamentally linked to mathematics, believing that musical harmony reflected universal order (Simoni, 2003). These ancient Greek "formalisms" however are rooted mostly in theory, and their strict application to musical performance itself is probably questionable (Grout and Palisca, 1996). Therefore, it can't really be said that Ancient Greek music composition was purely algorithmic in the sense we have defined it, but it undoubtably set the path towards important formal extra-human processes.

Ars Nova marked a pivotal shift in musical thought, where composers such as Philippe de Vitry and Guillaume de Machaut began to disentangle rhythm from pitch and text. By systematically applying rhythmic patterns—known as the *talea*—to fixed melodic cells called the *chroma*, they developed a method of composition that can be seen as an early form of algorithmic music-making (Simoni, 2003). This approach can be better understood by looking at Figures 2.2, 2.1 and 2.3, which

respectively represent the talea, chroma and the mapping between them of *De bon espoir-Puisque la douce-Speravi* by Guillaume de Machaut.

Figure 2.1: Talea of the isorhythmic motet *De bon espoir-Puisque la douce-Speravi* by Guillaume de Machaut

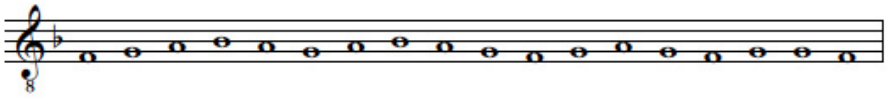

Figure 2.2: Color of the isorhythmic motet *De bon espoir-Puisque la douce-Speravi* by Guillaume de Machaut.

Figure 2.3: The tenor of *De bon espoir-Puisque la douce-Speravi* by Guillaume de Machaut

In the Renaissance and the Baroque periods, algorithmic methods became more explicit through forms like the canon, where composers, like Johann Sebastian Bach, created strict rules dictating how single melodies are to be imitated by multiple voices at different times.

A famous Classical-era example is Mozart's *Musikalisches Würfelspiel* ("Dice Music") in which musical phrases were randomly assembled by dice rolls to allow any composer to form a waltz, explicitly employing chance-based algorithmic composition (Maurer, 1999).

The 20th century introduced more complex algorithmic techniques through serialism, where composers like Arnold Schoenberg and Alban Berg employed systematic tone-row matrices (see Figure 2.4 to structure their compositions through fixed rules. Composers such as John Cage and Karlheinz Stockhausen later incorporated chance and probabilistic methods, further extending the tradition of algorithmic music before the advent of computers (Simoni, 2003).

2.1.2. Computer-Aided Methods

The advent of computers in the mid-20th century significantly advanced algorithmic composition, introducing computational techniques that expanded creative

possibilities. Early pioneers like Lejaren Hiller and Leonard Isaacson composed the *Illiac Suite* (1957), one of the first pieces generated entirely by computer algorithms (Hiller and Isaacson, 1959). They utilized a generator/modifier/selector framework, where musical materials were algorithmically created, modified, and selected based on predefined rules (Maurer, 1999).

Composer Iannis Xenakis introduced *stochastic music*, employing probabilistic methods to generate musical structures. For instance, in his work *Atrées* (1962), Xenakis used probability distributions and random number generators to determine musical elements (Xenakis, 1992).

Computer-aided algorithmic composition can be categorized into three main approaches:

1. Stochastic systems: they incorporate randomness, ranging from simple random note generation to complex applications of chaos theory and nonlinear dynamics (Nierhaus, 2009).

2. Rule-Based systems: these utilize explicitly defined compositional rules or grammars, similar to earlier non-computer methods like the Renaissance canons or serialist compositions we have talked about. Notable examples include William Schottstaedt's automatic species counterpoint program and Kemal Ebcioglu's CHORAL system, which generate music based on historical compositional rules (Cope, 1991).

3. Artificial Intelligence systems: these systems extend rule-based methods by allowing a computer to develop or evolve compositional rules autonomously. David Cope's Experiments in Musical Intelligence (EMI) exemplifies this approach, analyzing existing compositions to create new music emulating specific composers' styles (Maurer, 1999).

2.2. Non-symbolic music generation

In Section 2.1 we gave an overview of historical algorithmic composition along with its two main branches: non-computer-aided and computer-aided methods, which largely focus on *symbolic* or high-level approaches. In this section, however, we turn our attention to *non-symbolic* music generation, where the emphasis is on generating and shaping audio signals directly.

We begin with an overview of foundational digital synthesis systems, which provided the bedrock for modern audio generation. We then discuss recent AI-based approaches, including various deep-learning architectures capable of producing music at the waveform (or spectrogram) level. Although this thesis aims to ultimately employ a conditional variational autoencoder for generating musical notes, understanding the broader ecosystem of audio-focused methods places our work in context.

2.2.1. Traditional Synthesis Systems

2.2.1.1. Additive Synthesis

Additive synthesis is a sound creation method based on the Fourier Theorem, which states that any sound can be decomposed into a sum of sine waves, or partials (Fourier, 1822). By controlling the frequency, amplitude, and phase of each partial, one can construct complex timbres from these elementary components. Historically, this idea finds early expression in acoustic instruments such as the pipe organ (see Figure 2.5), where multiple pipes combine to produce rich harmonic textures, and in pioneering electronic devices like the Telharmonium—often considered one of the first additive synthesizers.

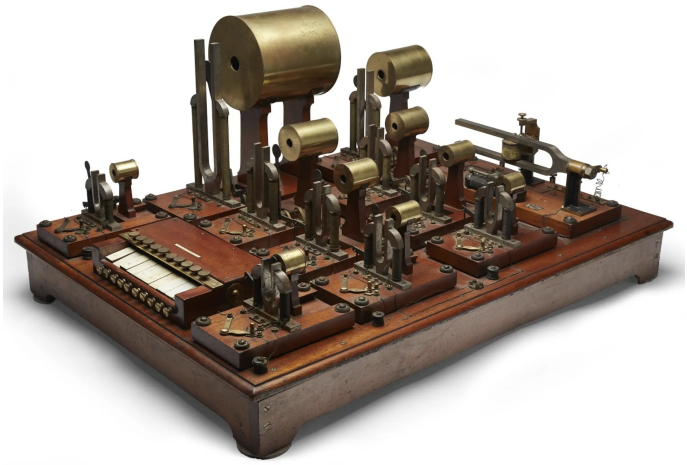

Figure 2.5: Pipe organ created by Hermann von Helmholtz around 1862

The method was further advanced in the mid-20th century through the work of Max Mathews at Bell Labs, who demonstrated the vast potential of digital addi-

tive synthesis for generating evolving and intricate soundscapes (Mathews, 1963). Although the flexibility of additive synthesis allows a precise crafting of any sound, its complexity made it less practical compared to the more cost-effective subtractive synthesis during the analog era. With the rise of digital signal processing, however, additive synthesis experienced a revival. This influenced the appearance of modern hybrid synthesizers that incorporate both additive and substractive techniques (Roads, 1996; Tagi, 2023a).

2.2.1.2. Subtractive Synthesis

Subtractive synthesis is one of the most widely used methods in sound synthesis systems. Conceptually, this approach is not harder to understand than additive synthesis: starting with a complex waveform as the raw material, we want to shape it by filtering out unwanted frequencies, much like sculpting a figure from a block of marble. What do we shape this raw signal with? Well, a substractive synthesizer primarily uses these components:

- Oscillators: is the responsible for generating the initial complex waveforms rich in harmonics.
- Filters: which remove (or subtract) selected frequency components. This can be done with filters such as the so-called low-pass or high-pass, which respectively remove high and low frequencies.
- Amplifiers and Envelope Generators: amplifiers control the overall level of the sound over time while an envelope generator is a tool that shapes how a sound evolves when a note is played by controlling four different dimensions (see Figure 2.6):

  1. Attack: how quickly the sound reaches its peak.
  2. Decay: how fast it drops from the peak to a steady level.
  3. Sustain: the level at which the sound holds while the note is sustained.
  4. Release: how rapidly the sound fades after the note is released.

  These simple stages allow you to craft sounds that can be sharp and percussive or smooth and evolving (Hahn, 2022).
- LFOs (Low-Frequency Oscillators): LFOs operate at very low frequencies that are below the threshold of human hearing and can create effects like vibrato or tremolo, therefore bringing the possibility of adding movement and life to a sound (Tagi, 2023c).

Historically, subtractive synthesis dates as back as 1930 with instruments such as the Trautonium and continued to be used throughout the 20th century, for example, by Robert Moog's Minimoog (Réveillac, 2024).

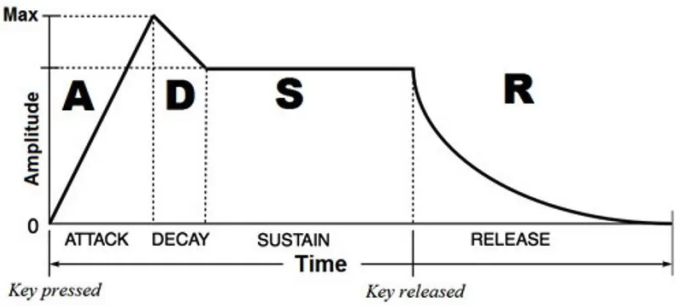

Figure 2.6: Illustration of Attack (A), Decay (D), Sustain (D) and Release (R)

2.2.1.3. Frequency Modulation (FM) Synthesis

Frequency modulation synthesis (FM synthesis) is a method of sound design in which one oscillator, known as the *modulator*, modulates the frequency of another oscillator, called the *carrier*, which allows to create new frequency components without filters (see Figure 2.7). In simple terms, rather than "sculpting" a sound by removing frequencies (as in subtractive synthesis), FM synthesis generates complex spectra by dynamically altering the pitch of a carrier with a modulating signal (Cymatics, 2025).

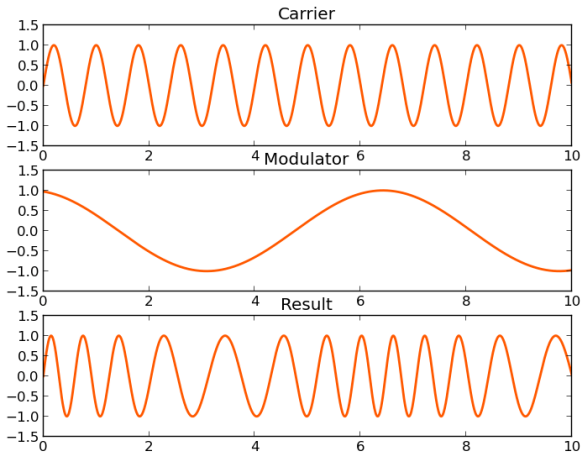

Figure 2.7: Illustration of a carrier, a modulator and the output

FM synthesis is the result of John Chowning's experiments in 1967 at Stanford University: by using sine waves (using one to modulate the frequency of another) Chowning discovered that a variety of new timbres could be generated. (Cymatics, 2025).

FM synthesis revolves around the building block of an *operator*, that typically includes an oscillator, an amplifier, and an envelope generator (recall we have talked about these in substractive synthesis). Operators can serve as carriers, modulators, or both, and they are arranged in various configurations or algorithms to produce different sound textures (Tagi, 2023b).

2.2.1.4. Other Approaches: Granular, Physical and Spectral Modeling

Beyond the traditional methods of additive, subtractive, and FM synthesis, there do exist other important and more modern sound generation techniques. We will very briefly talk about three of them.

Granular Synthesis works by breaking a sound into tiny segments called grains. These grains can then be individually rearranged to create a rich variety of sound textures, from subtle ambiences to complex, glitch-like effects (Roads, 1996).

Physical Modeling Synthesis takes a different route by simulating the behavior of real-world systems, such as vibrating strings, which allows for realistic emulations of acoustic instruments (Allen and McCreary, 1997).

Spectral Modeling involves analyzing a sound's frequency content (often with Fourier techniques) and then resynthesizing it by manipulating its spectral components. This way, interpolation and morphism between sounds can be achieved in a simpler way than with other traditional synthesis methods.(Serra, 1998).

2.2.2. Modern AI-Driven Non-Symbolic Music Generation

Unlike the traditional systems based on handcrafted signal-processing algorithms, deep learning methods for non-symbolic music generation learn representations directly from data. They typically produce raw audio waveforms or time-frequency representations, such as spectrograms. In recent years, several influential neural architectures have emerged, capable of generating musical audio directly at the waveform level. Our model will also follow this paradigm.

2.2.2.1. Waveform Modeling Approaches

WaveNet is a neural network initially designed for generating realistic speech audio directly from waveform samples. WaveNet operates by predicting each audio sample based on previously generated samples, using dilated causal convolutional layers. These dilations expand the receptive field, allowing the network to capture both fine-grained details and wider temporal context, which seems essential for modeling realistic audio textures. Although initially designed for text-to-speech synthesis, WaveNet was quickly adapted for music and demonstrated its effectiveness in capturing musical features at the waveform level (van den Oord et al., 2016).

Another significant development was the introduction of **SampleRNN** (Mehri et al., 2017), a hierarchical recurrent neural network (RNN) architecture specifically created to handle the complexity of raw audio generation. SampleRNN models waveforms at multiple temporal scales by stacking RNN layers hierarchically, allowing each layer to focus on different aspects of musical structure. Higher layers manage broader temporal dependencies, capturing long-term patterns, while lower layers handle local audio details. (Maurer, 1999).

Another significant breakthrough in non-symbolic music generation was achieved with **Generative Adversarial Networks (GANs)**. An important example is *GANSynth*, developed by *Google Magenta*, which synthesizes audio notes using generative adversarial networks operating in the frequency domain (Engel et al., 2019). Unlike WaveNet and SampleRNN, which sequentially generate each sample, GANSynth produces entire audio clips simultaneously by generating spectrograms and instantaneous frequency components. This approach results in more realistic and coherent musical timbres. Additionally, GANSynth allows for audio synthesis control, which enables independent manipulation of pitch and timbre, making musical creativity and composition easy.

Chapter 3

Basic musical concepts

[Explain basic musical concepts and put émphasis on those that the dataset uses]

Chapter 4

Introduction to Deep Learning and Conditional Variational Autoencoders

In this chapter, we will first sprovide the reader with a basic understanding of what Deep Learning is and its main components. The aim is not to go into detail but rather gain the necessary intuition to be able to grasp an end-to-end deep learning architecture. This will be useful for those who are introducing themselves in the topic to better comprehend our project and decisions within it.

Once we have done this, we will go a little further by explaining from both a broad and a detailed perspective the deep learning models and architectures we have used in this project: Convolutional Neural Networks, Autoencoders, Variational Autoencoders and Conditional Variational Autoencoders.

4.1. Deep Learning

Deep learning is a subset of machine learning that uses big neural networks to model complex patterns in data. A neural network consists of units called neurons, organized in layers: an input layer, one or more hidden layers, and an output layer. Each neuron applies a weighted sum of its inputs, adds a bias, and passes the result through a non-linear activation function.

A typical feed-forward pass through a single neuron can be expressed as:

$$z_j = \sum_i w_{ij}\, x_i + b_j, \quad a_j = \sigma(z_j), \tag{4.1}$$

where x_i denotes the inputs, w_{ij} are the weights connecting input i to neuron j, b_j is the bias term, z_j is the neuron's pre-activation, $\sigma(\cdot)$ is a non-linear activation function (such as ReLU, sigmoid, or tanh), and a_j is the neuron's output. Stacking many such neurons into multiple layers allows deep networks to learn hierarchical representations of data (Goodfellow et al., 2016).

If we want a model to learn about some data, we need to train it. Training a model involves finding the best weights and biases to minimize a loss function. This function measures how far off the model's predictions are from the actual targets. A common loss for regression problems is the Mean Squared Error (MSE):

$$\mathcal{L}_{\text{MSE}} = \frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2. \tag{4.2}$$

The optimization is usually done using gradient descent, a very well known machine learning algorithm that uses the backpropagation technique. During backpropagation, the chain rule is applied to propagate the error signal from the output layer back through the hidden layers, thereby adjusting each weight to reduce the overall error in a direction guided by the negative gradient of the loss. Thanks to it, weights are updated iteratively using an optimizer like stochastic gradient descent (SGD) or Adam.

In order to train and evaluate a deep learning architecture we need a dataset from which to gather data. This data is usually divided into three parts: training, validation, and test sets. The training set is used to learn the model parameters, the validation set is used to tune hyperparameters and avoid overfitting (situation where the model "memorizes" data instead of learning it), and the test set evaluates the model's generalization ability. There exist several ways to try to avoid overfitting, such as regularization or early stopping (Goodfellow et al., 2016).

4.2. Convolutional Neural Networks (CNNs)

Convolutional Neural Networks (CNNs) are a class of deep learning models particularly well-suited for data with a grid-like topology, such as images (2D grids of pixels) or audio spectrograms (2D time-frequency grids). A CNN introduces two key concepts: *local receptive fields* and *weight sharing*. Rather than connecting every input unit to every neuron in the next layer, as in a fully-connected network, a convolutional layer uses a small *filter*, also known as *kernel*, that slides across the input to produce feature maps. This filter is a learnable matrix of weights applied to local regions of the input, detecting specific local patterns (e.g., edges, textures) wherever they might appear. The same set of filter weights is reused for every location in the input (*convolution* and weight sharing), which greatly reduces the number of parameters and makes the model more efficient (LeCun et al., 1998; Krizhevsky et al., 2012).

A typical CNN architecture consists of an input layer, followed by repeated stacks of convolutional layers, activation functions (like ReLU), and pooling layers. Pooling layers aggregate information in local neighborhoods (for example taking the maximum or average of that region), reducing the spatial dimensions of the feature map and attempting to capture the most important characteristics of the data. Repeated convolution added to pooling operations allow the network to extract increasingly

abstract features at deeper layers, while gradually reducing dimensionality. Ultimately, one or more fully connected layers consolidate the extracted features for the final prediction (LeCun et al., 1998; Krizhevsky et al., 2012). A nice visual of a typical CNN architecture can be seen in Figure 4.1.

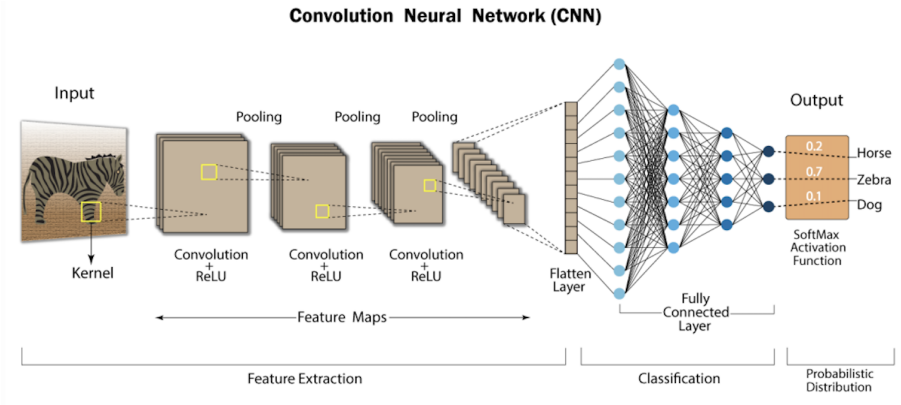

Figure 4.1: Typical CNN architecture

CNNs have been extremely successful in computer vision tasks. Classic examples include LeCun's LeNet-5 for handwritten digit recognition (LeCun et al., 1998) and the AlexNet network that won the 2012 ImageNet competition (Krizhevsky et al., 2012). Both architectures demonstrated the power of deep CNNs on large-scale image data.

In our project, we used CNN layers as the main components of the autoencoder, a type of network we will talk about in short time. In our case, CNNs were used to process spectrograms derived from the NSynth dataset (Engel et al., 2017). Spectrograms can be viewed as 2D representations of audio signals (time vs. frequency), and are therefore fit to convolutional operations.

Additionally, recent work has explored CNNs for interactive and explanatory purposes in various domains, including audio generation. For example, CNN Explainer (Wang et al., 2020)[1] demonstrates how convolutional kernels learn from image data, and similar principles extend to audio, where convolutional layers automatically discover patterns corresponding to timbral or temporal events.

4.3. Autoencoders

An autoencoder is a type of neural network made up of two main components: an *encoder* and a *decoder*. The encoder compresses the input x into a typically lower-dimensional latent representation h, and the decoder reconstructs an output $\hat{x}$ from this representation so that $\hat{x}$ closely matches the original input x (Michelucci, 2022; Bank et al., 2021). By minimizing a reconstruction loss between x and $\hat{x}$, the autoencoder is forced to learn the most salient features of the input. For example,

[1] This is a great resource to closely understand how CNNs work

a simple mean squared error (MSE) reconstruction loss is:

$$\mathcal{L}_{\text{AE}} = \|x - \hat{x}\|^2, \tag{4.3}$$

where $\|\cdot\|^2$ indicates element-wise squared difference.

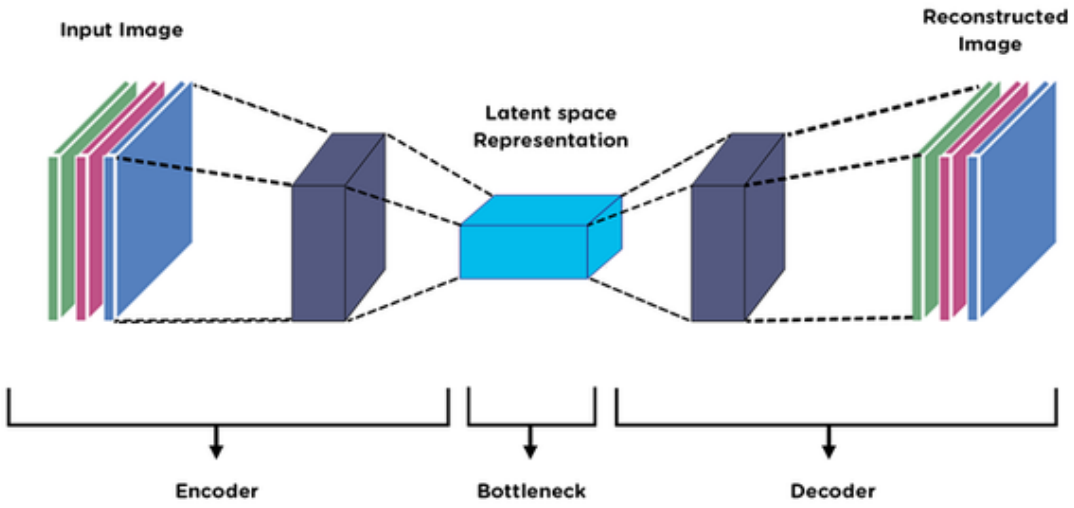

Figure 4.2: General structure of an autoencoder. The network consists of an encoder that compresses the input into a latent representation, and a decoder that reconstructs an output from it.

In the simplest form of autoencoder, both encoder and decoder are neural networks (often mirrored architectures) and h is a fixed-size vector (or tensor) of lower dimension than x. The hope is that h is an *informative* representation, meaning it captures the essential factors of variation in the data while discarding noise or irrelevant details. This learned latent space can then be useful for tasks like dimensionality reduction, visualization or anomaly detection (where high reconstruction error highlights anomalies).

There exists different types of autoencoders, and each of them serves a different functionality:

- **Denoising autoencoders** add noise to the input and train the model to reconstruct the original clean input, which encourages the network to learn robust features rather than simply memorizing the data (Michelucci, 2022).
- **Sparse autoencoders** impose a sparsity penalty on the latent representation, encouraging the network to use only a small number of active neurons for any given input. This often leads to the discovery of meaningful, disentangled features.
- **Convolutional autoencoders** apply convolutional layers in the encoder and decoder, which are especially effective for spatial or temporal data like images

or spectrograms, since they preserve local structure. In our project, we use a convolutional autoencoder to learn compact representations of musical notes, taking advantage of local patterns in audio spectrograms.

Ultimately, an autoencoder can learn an informative and compressed representation of data in an unsupervised manner. However, this deep learning architecture is not enough for the purposes of our thesis, since we want to be able to generate data from the learned distribution of samples. For this purpose, we now introduce the Variational Autoencoders.

4.3.1. Variational Autoencoders (VAEs)

A Variational Autoencoder (VAE) (Kingma and Welling, 2022) is a type of generative model that builds on the autoencoder architecture but with a probabilistic twist. In a standard autoencoder, the encoder produces a deterministic code $h = f(x)$. In a VAE, the encoder instead produces a probability distribution over the latent space. Typically, given an input x, the encoder (often called the inference network in this context) outputs parameters of a distribution $q_\phi(z|x)$ — usually a Gaussian with mean $\mu(x)$ and diagonal covariance $\sigma^2(x)$ — representing the probability of latent variable z given input x. We can think of this as the encoder no longer compressing x to a single point in latent space, but to a region of latent space (a Gaussian blob) characterized by μ and σ.

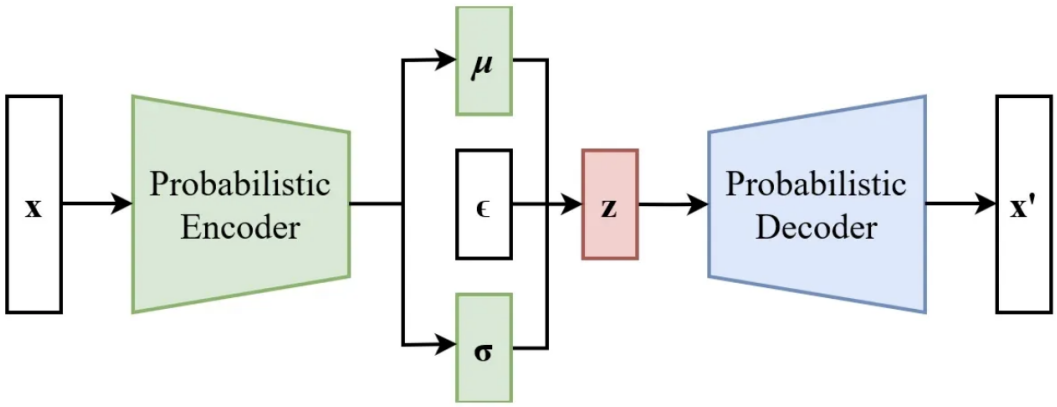

Figure 4.3: Variational Autoencoder architecture (with reparameterization trick). The encoder (green) maps an input x to parameters $\mu(x)$ and $\sigma(x)$ of a Gaussian distribution $q(z|x)$ over the latent variable z. A latent sample z is drawn (by combining μ, σ with a random noise ϵ) and passed through the decoder (blue) to produce a reconstruction x'.

In the generative process of a VAE, we assume some fixed prior distribution over z, usually a simple prior $p(z) = \mathcal{N}(0, I)$ (Kingma and Welling, 2022). The decoder, usually referred to as generative network, defines $p_\theta(x|z)$, the probability

of reconstructing x from latent z. Training a VAE involves maximizing the likelihood of the data under this generative model. However, directly maximizing the marginal likelihood $p_\theta(x) = \int p_\theta(x|z)p(z)dz$ is intractable due to the integral. VAEs address this by maximizing the evidence lower bound (ELBO), which is a substitute objective function that is easier to compute. The ELBO for a single data point x is:

$$\mathcal{L}(x;\theta,\phi) = \mathbb{E}_{q_\phi(z|x)}[\log p_\theta(x|z)] - \mathrm{KL}(q_\phi(z|x)\|p(z)) \tag{4.4}$$

This objective has two terms: a reconstruction term $\mathbb{E}_{q(z|x)}[\log p(x|z)]$ that encourages the decoder to reconstruct x accurately from sampled z, and a Kullback-Leibler (KL) divergence term $\mathrm{KL}(q(z|x)\|p(z))$ that regularizes the inferred latent distribution $q(z|x)$ to be close to the prior $p(z)$ (Kingma and Welling, 2022). Said in an informal manner, the Kullback-Leibler divergence term measures how much two probability distributions differ from one another.

One of the key innovations that makes VAEs trainable is the reparameterization trick (Kingma and Welling, 2022). Since sampling $z \sim q_\phi(z|x)$ is stochastic, we cannot directly backpropagate through a random sampling operation. The reparameterization trick circumvents this by expressing the sample z as a deterministic function of μ, σ, and a source of randomness ϵ that is independent of ϕ. For example, z can be obtained as:

$$z = \mu(x) + \sigma(x) \odot \epsilon, \quad \epsilon \sim \mathcal{N}(0, I) \tag{4.5}$$

Here $\odot$ is element-wise multiplication. In this way, the randomness ϵ is pulled out of the network, and the remaining operations are deterministic and differentiable with respect to ϕ (the encoder parameters that produce μ and σ).

By optimizing the ELBO, the VAE jointly learns the encoder parameters ϕ and decoder parameters θ. At convergence, the encoder $q_\phi(z|x)$ learns to approximate the posterior distribution of latent variables given data, and the decoder $p_\theta(x|z)$ learns to generate realistic data samples from latent codes. To generate new data, one can sample z from the prior $p(z)$ (e.g. draw a random vector from $\mathcal{N}(0, I)$) and then feed it into the decoder to obtain a sample x'. Because the latent space was regularized by the KL term, samples from the prior tend to produce valid outputs, and interpolation in the latent space yields smooth interpolations in the data space (Kingma and Welling, 2022). The result is a generative model capable of not only compressing data like a standard autoencoder, but also synthesizing new plausible data. VAEs have been used in image generation, text generation, and audio synthesis, among other domains, due to these generative capabilities (Michelucci, 2022).

4.3.2. Conditional Variational Autoencoders (CVAEs)

A Conditional Variational Autoencoder (CVAE) is an extension of the VAE that allows us to introduce conditioning information into the encoding/decoding process (Sohn et al., 2015). In many applications, we want to guide the generation process

with some additional input or context. For example, in our case, we might want to generate musical notes of a certain instrument or pitch. In a CVAE, we supply an extra variable c (the condition) to both the encoder and the decoder networks in order to modulate the latent space according to that context.

Concretely, the encoder in a CVAE models $q_\phi(z \mid x, c)$ and the decoder models $p_\theta(x \mid z, c)$. The condition c could be a class label, one-hot vector, or any auxiliary information relevant to the data. By providing c to the encoder, we allow the encoding of x to depend on the context c. By providing c to the decoder, we inform the generative process about what we want to generate. The training objective for a CVAE is similar to a standard VAE, except conditioned on c:

$$\mathcal{L}(x, c; \theta, \phi) = \mathbb{E}_{q_\phi(z|x,c)}[\log p_\theta(x|z, c)] - \mathrm{KL}(q_\phi(z|x, c)\|p(z|c)) \tag{4.6}$$

In practice, $p(z|c)$ is often taken as $\mathcal{N}(0, I)$ for all c.

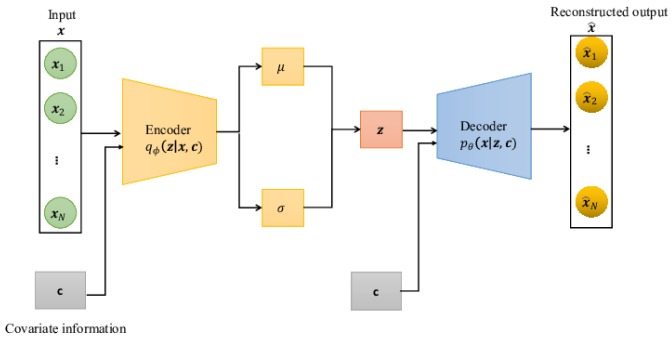

Figure 4.4: Conditional Variational Autoencoder architecture. The encoder (green) maps an input x and condition c to a latent distribution $q(z|x, c)$, and the decoder (blue) reconstructs the output x' conditioned on both z and c.

A significant benefit of the CVAE in our context is that it leverages label information to structure the latent space. In a vanilla VAE, the model might use part of the latent dimensions to encode information like "this is a piano" vs "this is a violin" if those instrument differences cause large variations in the input. The CVAE, given the instrument as input, can focus its latent dimensions on other characteristics (like timbral nuances or note dynamics), since it doesn't need to reinvent a code for the instrument identity — that's provided as c. This often leads to better utilization of the latent space and can improve generation quality for each class, because the model effectively trains separate (but related) generative pathways for each condition category (Sohn et al., 2015).

In our project, the use of a CVAE seems to be perfect for our purposes. We aim to generate musical notes from the NSynth dataset (Engel et al., 2017), and we want to be able to control certain attributes of the generated audio. The NSynth dataset consists of around 305,979 musical notes, each annotated with attributes like pitch (note), instrument type, velocity, and so on. We can thus train a CVAE that learns to generate, for example, a note of a given pitch played by a specified instrument.

Conclusions and Future Work

Conclusions and future lines of work. This chapter contains the translation of Chapter **??**.
